BOOK REVIEW

Optical Properties of Solids

E. D. Haidemenakis

The book contains twenty one papers presented at the International conference 'On the Optical Properties of Solids' held in Chania, Crete, Greece, from June 30 to July 10 of 1969. Topics discussed include theoretical and experimental reviews and recent results on interband transitions, excitons, submillimeter wavelength spectroscopy, new energy band calculations, polarons, the use of synchrotron radiation in the study of optical properties, atomic vibrations, fourier spectroscopy, magnetic crystal, photo-emission, modulated reflectance technique, magneto-optical studies in semiconductors and relativistic phenomena in semiconductors.

In the phenomenological theory of optical properties of a solid the complex dielectric constant \( \varepsilon = \varepsilon_1 - i\varepsilon_2 \) plays a fundamental role. Properties like refractive index, absorption coefficient, reflectance, photoemission etc., may be correlated to \( \varepsilon \). \( \varepsilon_1 \) and \( \varepsilon_2 \) however, are not independent. They are related by the well known Kramers-Kröning relation. Thus if \( \varepsilon_2 \) is known as a function of frequency \( \omega \), then all the dielectric properties of a medium are defined. Microscopic theory mainly concerns itself with the calculation of \( \varepsilon_2(\omega) \) from a knowledge of the characteristic excitation spectrum of the solid.

At visible or ultraviolet frequencies \( \varepsilon_2 \) is determined by the electronic interband transition energies. In Chapter 1, Bassani discusses a simple model which neglects correlation amongst electrons as also electron-hole interactions. The band structure is related to \( \varepsilon_2 \) and the result is applied to a number of layer lattice compounds. The theory however breaks down for alkali halides and rare gas solids for which the band gap is large and the electron-hole interaction is strong. Basacchi reviews the optical properties of alkali halides in the region \( h\omega < 10 \text{ ev} \) and discusses the possibility of interpreting the results in terms of band structure calculations and exciton theory. Hoensel describes the results of inner shell transitions in alkali halides obtained with synchrotron radiation in the range of 10 ev to 260 ev. Nilsson reviews the experimental results on \( \varepsilon_2(\omega) \) and also of the results of photoemission experiments on noble metals and some alloys. \( \varepsilon_2(\omega) \) is compared with theoretical curves obtained from energy band calculations.

In all these interpretations, the necessity of improved energy band calculation cannot be overemphasised. For every crystal it is necessary to have a self-consistent energy band calculation similar to the Hartree-Fock calculations for
atomic systems. But the complexity of the non-local H-F operator has so far stopped any one from doing a truly first principle calculation in crystals. In Chapter IV, Collins et al describe some approximate procedures which are listed on an atomic system (Kr) and also on a crystalline system (ZnS). Detailed comparison with experimental results are given for GaAs. The discussion is extended to metals by Lundqvist. He also discusses the many body effects in the spectra of simple metals.

Cyclotron resonance experiments are a powerful tool in the study of the properties of electrons in semiconductors. Experiments are generally done in microwave and lower frequencies. Wallis in Chapter XI discusses the theory of electron-photon-phonon interaction in presence of a magnetic field and its effect on C-R frequencies. But microwave spectroscopy cannot reveal the fine structure of absorption lines in the valence band, for which submillimeter molecular gas laser C-R spectroscopy is needed. The results of these experiments provide valuable information about the constant energy surfaces near the valence edge.

In polar crystals, electron-phonon interaction modifies the motion of the conduction electrons. The electron creates a cloud of virtual phonons around it and the complex system can be thought of as a quasi-particle called polaron. In these papers the theory of optical properties on polaron models are discussed.

Other papers include discussions on the effect of atomic vibrations on the optical properties of solids, infrared vibration frequencies of H-bond in ferroelectric KH$_2$PO$_4$ crystal, optical excitation of spin systems in magnetic crystals and relativistic phenomena in semiconductors.

The book gives a fairly comprehensive review of the works being carried out at present on some aspects of the optical properties of solids. The theoretical and experimental works get a balanced emphasis. Apart from critically evaluating the results so far achieved, attention is focussed on outstanding problems and the direction of future investigations. Articles contain exhaustive references to recent works.

The book under review will be valuable not only to those engaged in studies on topics discussed but also to those working in other related fields in solid state physics, who desire to be informed about the recent developments in these topics.
